Abstract

We have combined chemical and micrometeorological measurements to investigate the formation and distribution of HONO throughout a forest canopy. HONO was measured simultaneously at two heights, close to the forest floor and just above canopy. The turbulent exchange between the forest and the atmosphere above was studied using vertical profiles of eddy covariance measurements. HONO mixing ratios at both heights showed typical diel cycles with low daytime values (~80 ppt) and high nighttime values (up to 500 ppt), but were influenced by various sources and sinks leading to mixing ratio differences (above canopy minus below) of up to +240 ppt at nighttime. In the late afternoon and early night mixing ratios increased at higher rates near the forest floor, indicating a possible ground source. Due to the simultaneous decoupling of the forest from the air layer above the canopy, mixing ratio differences reached about −170 ppt. From the late night until the early morning mixing ratios above the forest were typically higher than close to the forest floor. For some cases, this could be attributed to advection above the forest, which only partly penetrated the canopy. Measured photolysis frequencies above and below the forest canopy differed by a factor of 10–25 resulting in HONO lifetimes of about 10 min above and 100–250 min below the canopy at noontime. However, these differences of the main daytime HONO sink were not evident in the mixing ratio differences, which were close to zero during the morning hours. Effective turbulent exchange due to a complete coupling of the forest to the air layer above the canopy in the morning has offset the differences caused by the daytime photolytic sink and added to the interplay between different HONO production and loss processes.

1 Introduction

Nitrous acid (HONO, HNO₂) is currently gaining substantial attention due to its contribution to the tropospheric OH radical production, which is the “cleansing detergent”
of the atmosphere. Besides its importance for the atmospheric oxidation potential, it contributes to acid and nutrient deposition to the biosphere. Moreover, growing concern exists about possible health effects due to the formation of nitrosamines (Hanst et al., 1977; Pitts et al., 1978) where HONO acts as the nitrosating agent, especially in indoor environments, e.g., so called third hand smoke after wall reactions of HONO with nicotine (Sleiman et al., 2010). Despite three decades of research since the first unequivocal detection of HONO in the atmosphere (Perner and Platt, 1979), HONO formation processes in the atmosphere are still under discussion, especially during daytime when large discrepancies were found between mixing ratios calculated from known gas-phase chemistry and measured daytime mixing ratios (Kleffmann et al., 2005). In the absence of light the most favoured formation reaction is the heterogeneous disproportionation of nitrogen dioxide (NO$_2$):

$$2\text{NO}_2 + \text{H}_2\text{O} \rightarrow \text{HONO} + \text{HNO}_3$$  \hspace{1cm} (R1)

This reaction has been extensively studied on different materials like fluorinated polymers and different types of glass as reviewed by Lammel and Cape (1996), but also on building materials like concrete (Trick, 2004). It was found to be first order in NO$_2$ and water vapour (Sakamaki et al., 1983; Pitts et al., 1984; Svennson et al., 1987; Jenkin et al., 1988). A mechanism involving the formation of the NO$_2$ dimer (N$_2$O$_4$) in the gas phase was proposed (Finlayson-Pitts et al., 2003), but is not of atmospheric relevance (Kleffmann et al., 1998; Gustafsson et al., 2008). Recently, evidence for a mechanism involving chemisorption of water on surfaces and reaction with adsorbed NO$_2$ (NO$_2$(ads)+H(ads)$\rightarrow$HONO(ads)) was found in a study on mineral dust particles with isotopically labelled water (Gustafsson et al., 2008), but the results are probably not transferable from laboratory to field conditions (Finlayson-Pitts, 2009). In the absence of light, HONO formation from NO$_2$ on soot decreases quite rapidly and thus was concluded not to be of atmospheric relevance except for freshly emitted soot (Kleffmann et al., 1999; Arens et al., 2001; Aubin and Abbatt, 2007). The mechanism was summarized as the Reaction (R2) of reducing organic compounds $\langle\text{C--H}\rangle_{\text{red}}$ with NO$_2$ (Gutzwiller et al., 2002a).

$$\text{NO}_2 + \langle\text{C--H}\rangle_{\text{red}} \rightarrow \text{HONO} + \langle\text{C}\rangle_{\text{ox}}$$  \hspace{1cm} (R2)

$$\text{NO} + \text{NO}_2 + \text{H}_2\text{O} \rightarrow 2\text{HONO}$$  \hspace{1cm} (R3)

$$\text{HNO}_3(\text{ads}) + \text{NO(}g\text{)} \rightarrow \text{HONO} + \text{NO}_2$$  \hspace{1cm} (R4)

A similar reaction like (R2) was postulated for the aqueous phase (Gutzwiller et al., 2002b; Ammann et al., 2005), but only proceeds at a relevant rate at high pH levels, since it is based on the well known charge transfer reaction of phenolate with NO$_2$. The Reactions (R3) (via the intermediate N$_2$O$_3$) and (R4), involving NO proposed from field measurements (Calvert et al., 1994; Andres-Hernandez et al., 1996; Saliba et al., 2001) could neither explain laboratory results under low NO$_2$ conditions (Svennson et al., 1987; Jenkin et al., 1988; Kleffmann et al., 1998, 2004) nor field experiments with low NO mixing ratios (Harrison and Kitto, 1994).

The daytime HONO formation recently discussed in an overview paper by Kleffmann (2007) was found to be about 60 times faster (Kleffmann et al., 2005) than the heterogeneous nighttime formation, and is even more controversial. There are a variety of proposed sources dealing with photoenhanced NO$_2$ reduction including NO$_2$ reduction on irradiated mineral surfaces like TiO$_2$ (Gustafsson et al., 2006; Ndour et al., 2008). Many studies focussed on the reduction of NO$_2$ involving organic photosensitizers (George et al., 2005) like hydrocarbons on soot (Monge et al., 2010) or humic acids (Stemmler et al., 2006, 2007). As already proposed from smog chamber experiments (Killus and Whitten, 1990), photolysis of deposited HNO$_3$/nitrate on surfaces was suggested as a daytime HONO source for rural environments by Zhou et al. (2002a,b, 2003) from field studies at low NO$_x$ conditions. The mechanism is still not convincing since the photolysis of HNO$_3$ was not found to be a photolytic source of HONO in chamber experiments (Rohrer et al., 2005). Quantum yields for HNO$_3$/nitrate photolysis are too low in the gas phase and in solution (Zhou et al. 2003; Kleffmann,
and matter between a forest ecosystem and the atmosphere. The "Weidenbrunnen" aerosol surface is of minor importance compared to the ground surface. Thus, the and chemical parameters were made in order to investigate the exchange of energy and chemical reactions in and above the forest canopy. In this paper, we have investigated HONO mixing ratio differences between above and below a forest canopy using the coupling processes by coherent exchange (Thomas and Foken, 2007) between different canopy layers and the air above the canopy. The definition of so-called coupling regimes is based on the detection of coherent structures, which are organized structures in the turbulent (stochastic) flow. For the first time, we demonstrate how measurements of HONO can be combined with a micrometeorological approach in tall vegetation, providing an appropriate tool to investigate processes affecting HONO mixing ratios measured within and above the canopy.

2 Experimental

During the Intensive Observation Periods (IOPs) of the EGER project (ExchanGE processes in a mountainous Region) simultaneous measurements of micrometeorological and chemical parameters were made in order to investigate the exchange of energy and matter between a forest ecosystem and the atmosphere. The “Weidenbrunnen”
research site is located in the Fichtelgebirge mountains in Northeast Bavaria (50° 9' N, 11° 52' E, 775 m a.s.l.), Germany, in a rural forested region. This site has been extensively studied by the University of Bayreuth (Matzner, 2004) and is a part of the FLUXNET (Baldocchi et al., 2001). Detailed information about the site has been given by Gerstberger et al. (2004). The site is covered by a Norway spruce (Picea abies (L.) Karst.) forest with a canopy height of 23–25 m (Staudt and Foken, 2007). A detailed description of the aims of the EGER project and the instrumental setup employed during the IOPs has been given by Foken et al. (2010). The measurements discussed in this paper were made at three different sites in the forest stand. A thin 38 m high tower ("turbulence tower") located about 60 m southeast of the main tower (31 m walk-up tower) was used for (undisturbed) turbulence measurements. The forest floor exchange site was located about 30 m northwest of the main tower.

Simultaneous measurements of HONO were conducted at a height of 24.5 m (just above canopy) on the main tower and close to the forest floor in 0.5 m at the forest floor exchange site from 13–25 September 2007. HONO was measured by two LOPAP instruments (LONG Path Absorption Photometer, QUMA Elektronik and Analytik, Wuppertal, Germany). The LOPAP is based on a wet chemical technique, with fast sampling of HONO as nitrite in a stripping coil and subsequent detection as an azo dye using long path absorption in 2.4 m long Teflon AF tubing. A detailed description of the instrument has been given by Heland et al. (2001) and Kleffmann et al. (2002). The instruments were placed outside in the forest or directly on the tower in ventilated aluminum boxes without temperature control. The temperature of the stripping coils was kept constant at 20 °C by thermostats to assure constant sampling conditions.

From 29 September to 3 October both LOPAPs were compared side-by-side near the forest floor at a height of 1 m. The sampling inlets had a distance of about 50 cm and were directed northwards to sample perpendicularly to the westerly flow. No T-piece was used as inlet to avoid artificial HONO formation or adsorption on the inner walls of the tubing. Both instruments were supplied with the same reagents via T-pieces.

Temperature and humidity profiles were measured at the main tower using Frankenberger-type psychrometers (Frankenberger, 1951). The relative humidity (RH) was calculated from the dry and wet bulb temperature of the psychrometers using the Magnus formula after Sonntag (1990) for the saturation vapour pressure and the Sprung formula for the actual vapour pressure (Foken, 2008). Psychrometers were mounted on the main tower at 0, 2, 5, 12, 21 and 32 m. Additionally, visibility was measured with a PWD11 (Vaisala, Vantaa, Finland) present weather detector mounted on the main tower.

Aerosol number size distributions were measured on the main tower at 28 m height using a Scanning Mobility Particle Sizer (SMPS, Grimm, Ainring, Germany). Boundary layer heights were derived from SODAR (SOUND Detection And Ranging, Metek Meteorologische Messtechnik, Elmshorn, Germany) measurements at a nearby clearing.

Vertical profiles of nitrogen oxides (NO and NO2) were measured on the main tower and on the forest floor exchange site by red-filtered detection of the chemiluminescence produced by the reaction of NO with O3 (CLD 780 TR, ECO Physics, Duernten, Switzerland). NO2 was photolytically converted to NO by exposure of the sample air to a solid-state blue-light converter (Meteorologie Consult, Königstein, Germany) and subsequently detected by the chemiluminescence analyzer. Sample air was drawn through 55 m of non-transparent and heated PFA tubing from each inlet height. Inlet heights of the system were located at 0.05, 0.3, 1, 2, 5, 10, 16, and 24 m. The lower heights of up to 2 m were located at the forest floor exchange site, while the upper heights were mounted at the main tower, for details see Moravek (2008).

To detect the coupling regimes between the subcanopy, canopy and layer above the canopy the eddy-covariance measurements were used. Six eddy-covariance systems consisting of a sonic anemometer and fast response CO2 and H2O gas analyzers were installed at the turbulence tower in 2.25, 5.5, 13, 18, 23 and 36 m. The wavelet transform was used to detect and extract ramp-like structures (coherent structures) from high frequency measurements of wind, sound temperature, CO2 and H2O concentrations (Thomas and Foken, 2005). These structures are responsible for the turbulent
coherent transport of the momentum and matter in forested ecosystems. Analysis of a sensible heat transport by coherent structures reveals the portions of the forest canopy coupled by coherent exchange with the air above the canopy (Thomas and Foken, 2007). The experimental setup and the analysis of the coupling regimes during the EGER intensive observation periods are described in more detail by Serafimovich et al. (2010).

The HONO photolysis frequency (\(j(HONO)\)) was calculated from the NO\(_2\) photolysis frequency measured by filter radiometers (Meteorologie consult, Königstein, Germany) according to Kraus and Hofzumahaus (1998) and Trebs et al. (2009). The radiometers were mounted on top of the main tower at a height of 28 m, and at 2 m above the forest floor at the forest floor exchange site.

For statistical computing the free statistics software “R” was used (http://www.R-project.org).

3 Results and discussion

3.1 Comparison of the two LOPAP instruments

The LOPAP instruments from the University of Bayreuth (UBAY) and the Max-Planck-Institute for Chemistry (MPIC) were compared side-by-side at 1 m above the forest floor between 27 September and 3 October to evaluate the precision of the instruments. For this purpose the relative differences of the measured HONO mixing ratios were calculated by normalizing the difference of \([HONO]_{UBAY} - [HONO]_{MPIC}\) by the arithmetic mean of these mixing ratios. The temporal evolution of these relative mixing ratio differences is shown in Fig. 1 together with the visibility as an indicator of foggy events. During rainy and foggy weather conditions indicated by the reduced visibility, we observed systematic deviations between the two LOPAP instruments. Large relative differences of the HONO signals during periods with low visibilities are related to fog events. Bröske et al. (2003) reported no measurable particle losses in the sampling glass coil for SOA (secondary organic aerosol) particles with diameters from 50–800 nm but Kleffmann et al. (2006) argued that large particles like fog droplets might be sampled by the coil. Thus, the sampling of fog droplets containing nitrite is a plausible explanation for deviations under wet conditions. However, this should affect both instruments by introducing more scatter and cannot explain the systematic deviation. Another potential reason could be that the surfaces of the sampling coils exhibited different wettabilities during these periods. During the dry conditions (visibilities of more than 2000 m, which is the maximum detectable by the instrument) between 29 September (14:00 CET) and 2 October (10:00 CET) HONO levels ranged from 35 ppt to 170 ppt and the instruments agreed within 12% (2\(\sigma\)), which is within the range of the estimated instrumental error under the given conditions (e.g., detection unit not air conditioned). Omitting the wet conditions before and after the dry period the relative errors correspond to a Gaussian distribution centred at zero. Thus, no systematic deviation of the instruments was found during dry conditions. The insert on Fig. 1 shows the correlation between the two instruments. Applying standard major axis regression analysis (Sokal and Rohlf, 1995; Legendre and Legendre, 1998), which is suitable for two random variables (e.g., Ayers, 2001) by reducing deviations perpendicularly to the regression line, yields an intercept of 2.3 ppt, which is close to the detection limit of the instruments (3\(\sigma\)-definition).

The slope is 0.97 and the coefficient of determination \(r^2 = 0.98\) for the dry weather period. Kleffmann (2006) used a T-piece and PFA tubing in front of the sampling units to compare two LOPAP instruments in order to avoid any influence from inhomogeneities in the sampled air. The linear correlation of these two LOPAPs was very good over a large mixing ratio range from about 200 ppt to 1.6 ppb, with a slope of 0.993 and an intercept of 1.4 ppt. However, since it is well known that any tubing in front of the sampling unit may cause artefacts due to wall reactions of NO\(_2\) we avoided this approach. Furthermore, there was no dependency of the relative error on the friction velocity (\(u^∗\)) or the horizontal wind speed, indicating no significant influence from inhomogeneities in the sampled air. This is expected because the sampling units were only about 50 cm apart. At wind speeds as low as 0.5 m s\(^{-1}\) it took only 1 s to pass both sampling units,
whereas the response time of both instruments is about 7 min. Thus, small scale inho-
mogeneities should contribute equally to both signals.

We conclude that the LOPAP instruments can be used to reliably measure vertical
HONO mixing ratio differences under dry conditions.

3.2 Factors controlling HONO mixing ratio levels

3.2.1 General observations in the time series

HONO is effectively scavenged by precipitation due to its good water solubility with
a Henry’s law constant of about 5 mol L$^{-1}$ atm$^{-1}$ (Sander, 1999). Precipitation was
found to structure the time series ranging from 13 of September to 3 October on a time
scale of about a week due to synoptic weather conditions (low and high pressure sys-
tems). Although not precisely measurable (see Sect. 3.1) due to large relative errors
of both instruments during foggy conditions, HONO values were clearly lower at both
heights during these wet periods. HONO:NO$_x$ ratios were below 2% at both heights
because (due to lower Henry’s law constants of NO (about 2x10$^{-3}$ mol L$^{-1}$ atm$^{-1}$) and
NO$_2$ (1-4x10$^{-7}$ mol L$^{-1}$ atm$^{-1}$) (Sander, 1999)) NO$_x$ is not significantly influenced by
precipitation scavenging or enhanced deposition on wet surfaces. During the entire
IOP, three dry periods occurred between rain events. Dry periods were character-
ized by steadily increasing nighttime HONO mixing ratios up to 500 ppt, while HONO
mixing ratios dropped during rain events to about 20 ppt. One of these dry periods (20–
25 September) is shown in Fig. 2. At the beginning of the dry period, HONO increased
continuously with a rate of about 2 ppt h$^{-1}$ without a pronounced diel cycle, although
the 20 September was a clear-sky day with $j$(HONO) values of about 0.002 s$^{-1}$ around
noon (see Fig. 3).

An increasing trend in both the time series of the HONO mixing ratio and the
HONO:NO$_x$ ratio is evident. To our knowledge this type of accumulation behaviour
was not reported so far, and it was not directly linked to an increase of the precursor
NO$_2$. Although clarifying the reason for this is far beyond our applied measurement

3.2.2 S/V$_{ground}$ versus S/V$_{aerosol}$

The needle surface also constitutes the largest fraction of the total ground surface.
Therefore, we estimated the ground surface from measurements of the projected plant
surface neglecting stem and understory contributions. The average PAI (Plant Area
Index) of this forest stand is 5 m$^2$ m$^{-2}$ (Staudt et al., 2010). This projected area can
be converted to a surface area by multiplying with $\pi$ for wooden parts (assuming they
are round), which contribute about 20% (5–35%, Gower et al., 1999) to the PAI and
by a factor of 2.65 derived by Oren et al. (1996) to convert the projected LAI (~80% of
PAI) to the geometric needle surface. From that simple scheme we derive a to-
tal geometric surface of the crown of 13.7 m$^2$ m$^{-2}$ (10.6 m$^2$ m$^{-2}$ needle surface and
3.6 m$^2$ m$^{-2}$ wooden surface). From SODAR (SOUND Detection And Ranging) mea-
surements we inferred an average NBL (Nocturnal Boundary Layer) height of 120 m by
a steep change in reflectivity of the sound signal. Using this value as an upper limit
for the volume (1 m$^2$ as base area), and for a lower limit ground surface the geometric
needle surface of the canopy, we get a S/V$_{ground}$ of 0.1 m$^{-1}$, which is an order of mag-
nitude higher than e.g. reported by Yu et al. (2009). However, Yu et al. (2009) took only
the inverse of the mixed layer height as S/V$_{ground}$, not accounting for any roughness of
the surface. Especially, during nighttime the boundary layer height represents an upper
limit for the volume, because mixing is very limited within the stable thermally stratified
NBL (Stull, 1988). Vogel et al. (2003) used a value of 0.1 m$^{-1}$ to model heterogeneous HONO production in the lowest box of their model but increased S/V$_{ground}$ to 0.3 m$^{-1}$, which matched the observations better. This is consistent with our observations that (S/V$_{ground}$) 0.1 m$^{-1}$ reflects a lower limit. In contrast, the S/V$_{ground}$ values given by Lammel and Cape (1996) were an order of magnitude higher, e.g., considering vegetation surfaces with 0.6–1.4 m$^{-1}$ (for a mixed layer height of 100 m). Additionally, we calculated the aerosol surface from the measured aerosol number size distributions and we found that S/V$_{aerosol}$ was typically less than 1% of S/V$_{ground}$, which implies that the contribution of aerosol surfaces to HONO formation can be neglected for our study.

A decrease of the boundary layer height increases S/V$_{ground}$. Hence, with the same surface more HONO is concentrated in a smaller volume. However, at the same time turbulence is suppressed during these stable conditions. This reduces the exchange between the atmosphere and the surface.

### 3.2.3 Nighttime HONO conversion frequencies

HONO nighttime conversion frequencies $F_{HONO\_night}$ from the heterogeneous disproportionation of NO$_2$ (cf. R1) can be estimated for the dry periods. Su et al. (2008) discussed the problem of different scaling methods for HONO production and suggested to use a combined scaling approach of different quantities emitted close to the ground like black carbon (HONO/BC) or carbon monoxide (HONO/CO), and the "classical" HONO/NO$_x$ or HONO/NO$_x$. The scaling was (originally) introduced to reduce influences from boundary layer processes such as dilution or vertical mixing. However, local sources of the scaling quantities will affect the ratio (Su et al., 2008). As discussed above, humid surfaces or precipitation will also alter the HONO/NO$_x$ ratio due to different solubilities as well as the advection of NO$_x$ from road traffic during the morning hours at our site. Due to the lack of carbon monoxide (CO) and black carbon (BC) measurements we use the NO$_x$ scaling approach, which was used in many other studies (e.g., Sjödin, 1988; Alicke et al., 2002; Kleffmann et al., 2003). The approach of Alicke et al. (2002) for inferring conversion frequencies, taking a linear increase of HONO during nighttime divided by the average NO$_2$ mixing ratio in this time interval is most commonly used.

$$F_{HONO\_night} = \frac{[HONO](t_2) - [HONO](t_1)}{(t_2 - t_1)[NO_2]_{night}}$$

(1)

There is still no reliable way of inferring HONO conversion frequencies using objective criteria. Yu et al. (2009) used a fixed time interval from 18:00 LT to midnight (local time) to determine HONO conversion frequencies. This approach leads to a very large scatter in our conversion frequencies. In addition, it yields mainly negative conversion frequencies in the lower height, because HONO increases already before sunset, thus starting at higher levels, and peak mixing ratios are reached before midnight. We also tried an approach different from the "classical" one, not using the maximum HONO mixing ratio as end point but the maximum HONO/NO$_x$ ratio that can be regarded as the maximum amount of HONO produced by NO$_x$.

1) Evaluating individual increases of HONO by the “classical” approach, excluding advection events and other disturbances

This approach could be used for evaluating data from five nights of the whole IOP (13–25 September) and yielded a value of $F_{HONO\_night}$±σ=(1.1±0.65)% h$^{-1}$ for the measurements above the canopy and a value of (0.75±0.45)% h$^{-1}$ close to the ground. The lower value for the lower height may be caused by choosing the starting point after sunset, whereas the first pronounced increase in HONO mixing ratios occurs already in the hours before sunset. Thus, the starting mixing ratio level is already higher at the lower height, whereas the increase at the upper height normally occurs later and is therefore completely captured. However, the influence of photochemistry has to be excluded for a proper comparison of heterogeneous production, and therefore we cannot use the data before sunset. The values of $F_{HONO\_night}$ at both heights agree within their standard deviation (variation over five nights) and are consistent with literature values.
between 0.4% h\(^{-1}\) and 1.8% h\(^{-1}\) recently summarized by Su et al. (2008). The value for the upper height also compares quite well with a value of 1.4 ± 0.4% h\(^{-1}\) reported by Yu et al. (2009), which was not included in the comparison by Su et al. (2008).

2) Evaluating the period from sunset to the maximum HONO/NO\(_x\) ratio

Conversion frequencies inferred by this approach are identical to the "classical" ones for the conditions during our campaign. The values and the variation of HONO/NO\(_x\) ratios were mainly correlated to HONO mixing ratios (see Fig. 4a,b). Therefore, the HONO/NO\(_x\) maxima occurred simultaneously with the maximum HONO mixing ratios (Fig. 2). Additionally, HONO mixing ratios were nearly independent of its precursor NO\(_2\) (see Fig. 4c). This was attributed to the fact that in contrast to studies in urban areas low NO\(_2\) mixing ratios were prevailing. About 90% of the NO\(_2\) values were below 5 ppb and 70% of the values ranged between 1 and 4 ppb, indicating quite constant NO\(_2\) levels. The highest HONO and HONO/NO\(_x\) values typically occurred before or around midnight (see Fig. 2) at moderate (2–5 ppb) NO\(_2\) mixing ratios, whereas the highest NO\(_x\) values occurred in the morning hours (advection from road traffic). The weak correlation of HONO to NO\(_x\) has already been observed in a field study at a rural forested site (Zhou et al. 2002a).

Nevertheless, conversion frequencies, as summarized above, are within the range of values reported in literature. Referring to the different conditions and methods used in these experiments, this range is astonishing narrow and might provide some guidance for modelling studies.

3.3 HONO mixing ratio differences and coupling regimes

The investigation of the coupling regimes of the forest to the air layer above the canopy, as well as the coupling inside the forest is crucial to study the surface-atmosphere exchange of trace gases. The shaded and more humid subcanopy featured different environmental conditions than the atmosphere above the canopy, where the humidity was lower and photochemistry was more active. Vertical mixing processes link these two environments. As an indicator for the effectiveness of vertical mixing, the detection of coherent structures was used. These provide effective mixing and can be used to infer the coupling between the subcanopy, canopy and the layer above canopy. Thomas and Foken (2007) defined five different coupling regimes:

- **Wave motion (Wa).** The flow above the canopy is dominated by linear wave motion rather than by turbulence, and therefore decoupled from the subcanopy and the canopy. Decoupled canopy (Dc). The air above the canopy is decoupled from the canopy, because there is no transfer of energy and matter into and out of the canopy by coherent structures.
- Decoupled subcanopy (Ds). The layer above the canopy is coupled to the canopy, but decoupled from the subcanopy.
- **Coupled sub canopy by sweeps (Cs).** The coherent exchange between the canopy air and the subcanopy is forced by strong sweep motion of coherent structures only.
- **Fully coupled canopy (C).** The layer above the canopy, the canopy and the subcanopy are in a fully coupled state.

The diel cycle of HONO mixing ratio differences (above canopy minus below canopy) shown in Figs. 5 and 6 can be subdivided into four typical periods:

1) Early night (17:30–21:00 CET): There was no photolytic sink (sunset at 17:30 CET), but also no turbulent exchange (Wa). These were from a micrometeorological perspective the most stable conditions during the day, with a complete decoupling of the forest from the layer above the canopy (Wa, Dc). Due to the increasing nighttime values in the dry period, absolute HONO differences increased as well and induce a higher variability at nighttime (Fig. 5). Mixing ratio differences of up to ~170 ppt ppt were measured. The higher HONO mixing ratios close to the forest floor in the early night can be explained by formation of HONO at the ground surface and accumulation in the trunk space, since the exchange with the layer above the canopy was very limited due to the decoupling of the forest. Above the canopy, mixing ratios increased at a lower rate or were fairly...
constant during this period, resulting in negative mixing ratio differences. The increasing differences could be observed similarly in the RH (Fig. 5), which was not affected by photolysis or chemical reactions. The sign of the difference changed during the early night at about 21:00 CET, when mixing ratios above canopy rose quickly and exceeded the values measured near the ground. This effect was more pronounced at the end of the dry period, when nighttime maximum values were much higher than during the first two days after the rain event.

2) Late night to early morning (21:00–06:30 CET): Increasing mixing ratios above the canopy, exceeding the values below the canopy caused positive mixing ratio differences (max. ∼240 ppt). The higher mixing ratios above the canopy from the late night to the early morning were either caused by advection of HONO-enriched air masses above the forest canopy (which was the case for high mixing ratios on 23 September) or potentially by wetting of the canopy and release of adsorbed HONO according to the mechanism described by Trick (2004).

3) Early morning to noon (06:30–13:00 CET): HONO mixing ratios decreased at both heights due to photolysis. The mixing ratio differences were close to zero (within the uncertainty of both instruments, see Sect. 3.1), although photolytic lifetimes differ by a factor of 10–25 (median values) between both heights (Fig. 6). Around noon of clear-sky days, lifetimes were about 10 min above and 100–250 min below the canopy. If no exchange between both heights had occurred, a steep mixing ratio gradient should be observed. However, coupling of all forest compartments to the layer above the canopy was achieved during this period, as indicated by the dominance of C and Cs regimes with Ds intermissions (Fig. 5). Hence, effective mixing has offset the differences in HONO lifetimes due to photolysis (Fig. 6).

4) Afternoon (13:00–17:30 CET): When decoupling of the subcanopy (Ds) became the predominant regime in the early afternoon (13:00) and HONO lifetime ratios increased to a factor of 25–40 (median values), we always measured negative mixing ratio differences with a surprisingly low variation over the entire dry period (Figs. 5 and 6).

The HONO/NO\textsubscript{x} vertical differences (not shown) have a similar diel cycle (see Figs. 5 and 6), as variations were mainly caused by the HONO mixing ratios (see Sect. 3.2). Differences were in the range of −6% (evening) to +5% (at night) and around zero from early morning to noon (very similar to HONO itself). Therefore, changes in the HONO mixing ratio differences can be attributed to changes in source or sink processes leading to higher (or lower) values in relation to NO\textsubscript{x} values. Under conditions with virtually no turbulent exchange of the forest with the layer above canopy (Dc and Wa regimes), which occurred in the late afternoon/early night we found systematically higher values below canopy. This is a strong indication that HONO was formed and/or released at the ground.

The diel cycle of the mixing ratio differences can be explained by differences in source and sink processes throughout the canopy, whereas the magnitude of these mixing ratio differences is determined by the exchange conditions as derived from the coherent structures.

3.4 Case study: 23 September

In order to exemplify the interplay of different HONO source and sink processes, Fig. 7 shows a contour plot of RH and the HONO mixing ratios measured at 0.5 and 24.5 m above the ground on 23 September.

From midnight to 06:30 CET, HONO mixing ratios were typically higher above the canopy than below. The HONO/NO\textsubscript{x} ratios were between 6 and 10% at both heights. We found a positive correlation ($r^2=0.78$) with RH at 24.5 m but no correlation at the lower height ($r^2=0.07$) during the same time period. This might be attributed to higher RHs up to 90% at the ground, representing a transition to a completely wetted vegetation surface (i.e. formation of epicuticular water films) above 90% RH (Burkhardt and Eiden, 1994; Klemm et al., 1998; Lammel, 1999) thus leading to HONO uptake.
During the first two hours after sunrise (06:30–08:30 CET), HONO mixing ratios decreased continuously with a rate of 60 ppt h\(^{-1}\) above the canopy and with 40 ppt h\(^{-1}\) close to the forest floor. If only photolysis was active, the calculated loss rate (i.e., \(j(HONO)\times[HONO]\)) above the canopy would be faster (76 ppt h\(^{-1}\)) than observed. Below the canopy, the calculated loss rate would be much slower (5.5 ppt h\(^{-1}\)) due to shading. This discrepancy can be explained by vertical mixing. Downward mixing of HONO-depleted air from aloft resulted in a much faster loss rate below the canopy than calculated from photolysis alone. The overall HONO loss is expected to be faster than the photolytic loss alone since the mixed layer growth in the morning contributes to a decrease of near surface HONO that was trapped in the thermodynamically stable NBL.

From 08:30 CET until noontime, slightly decreasing HONO mixing ratios (10–15 ppt h\(^{-1}\) most likely due to photolysis and mixing) were accompanied by a fast decrease of RH by 6% h\(^{-1}\) due to surface heating, causing rising surface temperatures. Therefore both measured variables were well correlated, but the correlation was mainly driven by radiation. Even though HONO lifetimes above and below canopy differ by a factor of 10 to 25 (median values) in the morning (Fig. 6), the difference in HONO mixing ratios is less than 5 ppt from 10:00–12:00 CET, which is within the uncertainty of both instruments. This can be explained by vertical exchange, taking place within the HONO lifetime above canopy.

Just after noontime, we observed a pronounced increase of HONO mixing ratios and of HONO/NO\(_x\) ratios at both heights, with a simultaneous increase of RH by 10%. These patterns were most likely caused by passing clouds, increasing the HONO lifetime by a factor of three (from 9 min to 26 min above canopy, see Fig. 3), but were also related to a change in wind direction.

After the noontime peak, HONO mixing ratios decreased again at both heights but with a lower rate below canopy due to the 10 times lower photolysis frequencies. Further increases of lifetime ratios in the afternoon from 25 to 40 may have contributed to the increasing differences. While these differences were counter-balanced by effective vertical mixing as indicated by a predominantly full coupling of the forest to the air layer above the canopy (C, Cs) in the morning hours, in the afternoon the HONO mixing ratio differences were maintained due to a lack of vertical mixing in the decoupled subcanopy (Ds) regime. Thus, only during periods when the subcanopy or even the whole forest are decoupled from the layer above the canopy, the different loss and production processes acting close to the forest floor and in the upper canopy become obvious. We propose a combination of lifetime differences due to shading of the canopy and the intensity of vertical mixing to explain the observed mixing ratio differences during daytime.

About two hours before sunset, HONO mixing ratios started to increase at both measurement heights. Above canopy, an increase rate of 40 ppt h\(^{-1}\) led to a slightly higher level of HONO mixing ratios of 70±16 ppt, whereas close to the forest floor, an increase rate of about 90 ppt h\(^{-1}\) resulted in a higher and nearly constant level of about 200±20 ppt. The steep increase in HONO mixing ratios at the ground coincided with an obvious RH increase below canopy, which is not as pronounced as above canopy. After sunset, photolysis does no longer affect the atmospheric lifetime of HONO. Thus, the occurrence of different HONO mixing ratios and at the same time different HONO/NO\(_x\) ratios (about 5% higher below canopy) at the two measuring heights provide evidence for different HONO-source processes throughout the canopy. The slight increase above the canopy and the strong increase below canopy in the absence of solar radiation and turbulent exchange with the air layer above canopy (Wa) give a strong indication that HONO was formed and released at the ground. We found a good correlation (\(r^2=0.74\)) of HONO and RH for the whole period from 16:00–20:30 CET close to the forest floor due to accumulation of HONO and humidity below the canopy after decoupling of the forest. Above the canopy the correlation coefficient is very weak (\(r^2=0.3\)).

Between 20:30–21:00 CET a steep increase of HONO mixing ratios was observed. This event is considered to be dominated by an air mass change and not by local HONO production or release. Simultaneously, ozone mixing ratios dropped by about
20 ppb (at 24.5 m), RH increased by 16% from 20:30–22:00 CET and NO\textsubscript{x} increased from about 2–4.5 ppb. Maximum HONO mixing ratios were reached at 21:30 CET with 480 ppt above and 340 ppt below the canopy. This resulted in HONO/NO\textsubscript{x} ratios of up to 18% above the canopy.

After 21:00 CET, the HONO mixing ratios decreased again at both heights while RH continued to increase. Thus, a negative RH dependence was observed with coefficients of determination of 0.9 at 24.5 m height (RH=78–85%) and 0.94 at 0.5 m height (RH=88–93%). The slopes are nearly identical but the humidity range is very different. Therefore, it is speculative at best to draw any conclusions about the underlying physical or chemical processes. Although we often found a good correlation of HONO and RH, we could not infer a simple relationship between RH and HONO mixing ratios. One reason for this is that both quantities exhibited a diel cycle that was affected by different (independent) environmental factors e.g. radiation. HONO was formed near the ground and accumulated during nighttime, whereas RH increased due to cooling of the surface and evaporation still occurring in the afternoon and subsequent accumulation.

During daytime HONO was photolyzed, whereas RH decreased due to surface heating although evaporation is enhanced. HONO and RH both decreased during daytime due to dilution by mixing with dryer and HONO depleted air from aloft. The only obvious relation are declining HONO mixing ratios at RHs above 95% as already observed by Yu et al. (2009).

4 Conclusions

For the first time, we have measured HONO mixing ratios simultaneously at two heights within and above a forest canopy using interference-corrected wet chemical analyzers (two LOPAP instruments). The instruments agreed within 12% (2\sigma) during side-by-side measurements under fair and relatively dry weather periods, allowing for a detailed interpretation of the measured mixing ratio differences. The measured HONO mixing ratios were influenced by a combination of several processes, such as a) available surface area for heterogeneous formation, b) co-deposition of species related to HONO formation, c) HONO desorption from the surface and interaction with RH and d) turbulent exchange of air masses between the forest and the atmosphere above (coupling).

The combination of micrometeorological and chemical measurements allowed us to explain the diel variations of the HONO mixing ratio differences measured below and above a spruce forest canopy. Differences of source or sink processes between above and below canopy became obvious only during periods when they were not overcome by turbulent mixing. For example, rising mixing ratios close to the forest floor in the late afternoon and early night, when the forest canopy was decoupled from the air layer above, provided a clear indication of HONO formation at the ground surface. Higher mixing ratios above the forest canopy in the late night until the morning were in some cases due to advection above the forest, which did only partly penetrate the canopy. In the morning, vertical exchange was most effective and thus differences in HONO mixing ratios varied around zero despite large differences of photolysis frequencies (factor of 10–25) below and above the canopy.

Moreover, we observed a build-up of HONO during dry periods that was not related to a build-up of its precursor NO\textsubscript{2}. We could not infer a simple relationship between RH and HONO mixing ratios. This study particularly demonstrated the strong effect of turbulent vertical transport and the influence of humidity conditions on HONO mixing ratios within and above the forest canopy. Nevertheless, in order to further untangle and quantify all different HONO sources and sinks, additional measurements both in the laboratory and in the field are required.

Fig. 1. Side-by-side measurements of the two LOPAP instruments from 27 September (noon) to 3 October 2007 (noon) at the “Weidenbrunnen” research site. Relative differences of the HONO signals (black dots) and visibility range (red squares, dashed lines, maximum range 2000 m). The insert shows the regression obtained during dry conditions ($N=247$) from 29 September (14:00 CET) to 2 October (10:00 CET) using standard major axis (SMA) regression. Missing values are due to zero air measurements and calibration of the LOPAP instruments.

Fig. 2. Time series of HONO at 0.5 m above the forest floor (triangles and blue line) and HONO/NO$_X$ ratio (black dotted line) from 18 (00:00 CET) to 26 (00:00 CET) September 2007 at the “Weidenbrunnen” research site. This dry period was delimited by rain events marked with grey circles (half hourly values).
Fig. 3. Time series of the HONO photolysis frequency $j$(HONO) parameterized from the measured NO$_2$ photolysis frequency at a height of 28 m (orange line and dots) and relative humidity measured at the canopy top (21 m) from 18 (00:00 CET) to 26 (00:00 CET) September 2007 at the “Weidenbrunnen” research site.

Fig. 4. Relationships of HONO and NO$_x$ for the measurement height close to the forest floor (0.5 m) for the period 13–25 September at the “Weidenbrunnen” research site. The upper graphs (a and b) show a better correlation of HONO/NO$_x$ to HONO than to 1/NO$_x$, i.e. variations in HONO/NO$_x$ are more likely explained by variations in HONO mixing ratios than by NO$_x$ values. The lower graph shows that HONO and its precursor NO$_2$ are not well correlated during the period from 13–25 September.
Fig. 5. Box-and-whisker plot for coupling regimes (red open bars) and HONO mixing ratio differences (grey filled bars) for the five-day dry period 20–25 September 2007 at the "Weidenbrunnen" research site. The upper panel shows the RH difference between 21 m and the forest floor for comparison (without outliers). The upper end of the boxes represents the 75th percentile, the lower end the 25th percentile and the line within the boxes the median. Whiskers denote the last values within the 10th (lower whisker) and 90th (upper whisker) percentiles. Outliers are marked as points (HONO difference) or squares (coupling regimes). If only whiskers appear, there are no other values between the values marked by the whiskers. From 08:00–14:00 CET there are only C and Ds values but with odd (08:00 CET and 12:00 CET) and even (10:00 CET and 14:00 CET) data points. The median therefore falls in line with the end of the box ("odd-case") or into the middle ("even-case").

Fig. 6. HONO mixing ratio differences (grey bars, 10 min averages) and lifetime ratios (below to above canopy) (red bars, 30 min averages) for the five-day dry period 20–25 September 2007 at the "Weidenbrunnen" research site. The upper end of the boxes represents the 75th percentile, the lower end the 25th percentile and the line within the boxes the median.
Fig. 7. Simultaneous HONO time series at 0.5 m (lower graph, circles and lines) and 24.5 m (upper graph, circles and lines), overlaid with a contour plot of the vertical profile of measured RH (colour-coded 50–92%) for 23 September 2007 at the “Weidenbrunnen” research site. Missing values in the HONO measurements are due to zero air measurements. Sunrise and sunset (inferred from $j$(NO$_2$) as a proxy for $j$(HONO) and global radiation measurements) are marked as vertical (orange) lines.
